(54) Particle size measuring device.

(57) The device includes a laser (21) photo-sensors (23) for measuring the spatial intensity distribution of diffracting and scattering light from the specimen (22), an arithmetic unit (24) for calculating particle size distribution, a first judging means (25) for monitoring outputs from selected photo-sensors so as to see if the monitored outputs exceed a first reference (X_1) so as to know that the specimen is present in the optical system, a second judging means (26) for storing the outputs of all the photo-sensors when the specimen is present in the optical system, and seeing if a maximum value of the outputs falls within a range defined by a second and a third reference ($X_2 - X_3$) so as to know that the concentration of the specimen is optimal for measuring, a storage (28) for storing the outputs of all the photo-sensors as effective data only when the maximum value falls within the reference range, a third judging means (27) for seeing if predetermined sets of effective data have been stored in the storage, wherein the arithmetic unit is operated when it is found that the predetermined sets of effective data are stored in the storage.

Fig. 1

FIELD OF THE INVENTION

The present invention relates generally to a device for measuring particle size distribution of powdery solids by utilizing diffracting and scattering light that occurs owing to the presence of the powdery solids. The measuring device is particularly adapted for measuring particle size distribution of powdery solids in a dry state.

BACKGROUND OF THE INVENTION

It is known in the art that the particle size distribution of powdery solids is measured by utilizing light diffraction singly or diffraction and light scattering jointly each of which tends to occur when powdery solids afloat in dispersion is irradiated with laser beam. More specifically, the laser beam diffracts and scatters owing to the presence of powdery solids, and the spatial intensity distribution of the diffracting and scattering light is detected by photo-sensors such as ring detectors. The resulting data are converted into particle size distribution in terms of functions based on the Fraunhofer's diffraction theory or the Mie light scattering theory.

The known measuring devices necessarily uses a liquid dispersion agent so as to disperse the powdery solids, hereinafter referred to as "specimen", and the method using a liquid dispersing agent will be referred to as "wet measuring method". If the specimen is a type which tends to become dissolved or hardened at the presence of liquid, which is common with medicinal substances and cement, a liquid dispersing agent is substituted by air, hereinafter referred to as "dry measuring method".

In order to carry out the dry measuring method, a group of particles are obtained as a specimen from the powdery solids by dispersing them into a misty state (hereinafter called "aerosol particles") and the aerosol particles are irradiated with laser beam.

This known measuring method requires that the specimen has a constant concentration in a predetermined range.

The wet measuring method makes it easy to homogeneously disperse the specimen, and to maintain the concentration of it within a required range. The dry measuring method is difficult to keep the concentration of specimen in a particular range unless a special sampling device is employed. Even though a special sampling device is employed, the concentration of specimen is difficult to maintain because of unexpected factors such as unstable pneumatic pressure, improper handling of the sampling device and malfunction thereof. There are a kind of powders whose concentration is inherently unstable after they are ejected in aerosol, which results in imprecise measurement.

SUMMARY OF THE INVENTION

The present invention is directed to overcome the difficulty in measuring the particle size distribution of powdery solids in a dry state regardless of any change in the concentration thereof.

According to the present invention, the measuring device includes a laser for radiating laser beam upon a specimen, an optical measuring system comprising a plurality of photo-sensors for measuring the intensity distribution of diffracting and scattering light upon the specimen, an arithmetic unit for calculating particle size distribution of the specimen on the basis of the intensity distribution measured by the optical measuring system, a first judging means for monitoring outputs from a predetermined number of photo-sensors and seeing if the monitored outputs exceed a first reference so as to know that the specimen is present in the optical measuring system, a second judging means for storing the outputs of all the photo-sensors after the first judging means ascertains that the specimen is present in the optical measuring system, and seeing if a maximum value of the outputs falls between a second reference and a third reference so as to know that the concentration of the specimen is optimal for measuring, a storage for storing the outputs of all the photo-sensors as effective data when the second judging means ascertains that the maximum value is present between the second and third reference, a third judging means for seeing if predetermined sets of effective data have been stored in the storage, and wherein the arithmetic unit is performed when predetermined sets of effective data have been stored in the storage.

BRIEF DESCRIPTION OF THE DRAWINGS

This invention may be better understood and its numerous objects and advantages will become apparent to those skilled in the art by reference to the accompanying drawings as follows:

Figure 1 is an explanatory view exemplifying the principle underlying the present invention;
 Figures 2 is an explanatory view showing another example of the embodiment;
 Figure 3 is a diagrammatical view showing the structure of an embodiment according to the present invention;
 Figure 4 is a front view showing ring detectors used in the present invention;
 Figure 5 is a flowchart showing a program written in a computer incorporated in the present invention; and
 Figure 6 is a graph showing a relationship between concentration and maximum values of outputs from photo-sensors in a dry measuring method under the present invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT

Referring to Figure 1, the basic principle underlying the present invention will be described:

There is provided a laser 21 which generates laser beam against a group of powder solids (specimen) 22. The laser beam diffracts and scatters owing to the presence of the specimen 22, and the spatial intensity distribution of diffracting and scattering light is measured by photo-sensors 23. The spatial intensity distribution is arithmetically processed so as to convert into the particle size distribution of the specimen. There are three judging means 25, 26 and 27 and a storage 28. The data of the spatial intensity distribution of diffracting and scattering light are selected in accordance with the results of each judging means 25, 26 and 27, and the effective data alone are stored in the storage 28. After the storage 28 stores predetermined sets of effective data, they are converted into the particle size distribution of the specimen by an arithmetic unit 24.

More specifically, the first judging means 25 monitors outputs of a predetermined number of photo-sensors 23 so as to see if they exceed a first reference value X_1 and ascertain that the specimen is present in the optical measuring system. The second judging means 26 monitors the outputs of all the photo-sensors 23, and sees if the maximum value falls within a range defined by a second reference value X_2 and a third reference value X_3 , thereby ascertaining that the concentration of the specimen falls within the required range. The storage 28 stores the outputs of all the photo-sensors 23 as effective data only when the second judging means 26 ascertains that the maximum value falls within the required range, that is, between the second reference value X_2 and the third reference value X_3 . The third judging means 27 sees if predetermined sets of effective data have been stored.

The relations between the maximum value of all the outputs of the photo-sensors 23 and the existing concentration of the specimen are depicted in straight line as shown in Figure 5.

Thus, even if the concentration of aerosol particles varies, the storage 28 stores the spatial intensity distributions of diffracting and scattering light that are obtained so long as the concentration of the specimen falls within the required range. When desired sets of effective data are stored, the stored data are converted into the particle size distribution of the specimen.

An alternative embodiment shown in Figure 2 is additionally provided with a fourth judging means 29 located subsequent to the second judging means 26. The fourth judging means 29 compares the maximum output A_{max} of those of all the photo-sensors 23 with the maximum output B_{max} of them in the correspond-

ing previous situation where the second judging means 26 ascertains that the concentration of the specimen falls within the required range. The fourth judging means 29 sees if the difference ($A_{max} - B_{max}$) between the values A_{max} and B_{max} remains within a fourth value X_4 . When the difference remains within the fourth value X_4 , the outputs of all the photo-sensors 23 are stored in the storage 28 as effective data on the spatial intensity distribution of diffracting and scattering light.

The addition of the fourth judging means 29 is advantageous in widening the reference range $X_2 - X_3$ so as to enable the second judging means 26 to judge the concentration of specimen in a wider range.

Referring to Figure 3, the structure of the measuring device according to the present invention will be described, wherein different numerals from those in Figures 1 and 2 are used to designate the same components:

An ejector 1 includes an air inlet 1a connected to an air compressor (not shown), a powdery solids supply port 1b located adjacent to a powder supplier 2, and a powdery solids outlet 1c through which powdery solids (A) are ejected in aerosol under pneumatic compression through the air inlet 1a. The aerosol particles (A) are ejected by the ejector 1 toward a collector 3, and are collected therein.

An optical measuring system is placed in such a manner that the optical axis (L) is located between the outlet 1c and the collector 3. A laser 4 generates a flux of laser beam against the aerosol particles through a beam flux forming optical system 5 (hereinafter referred to as "optical system") wherein the flux of laser beam has a predetermined cross-sectional area in parallel with the optical axis (L). A condenser lens 6 and a ring detector 7 are located on the optical axis (L) on the opposite side of the optical system 5 with the aerosol particles (A) interposed therebetween, wherein the ring detector 7 is located on the focal surface of the condenser lens 6. The ring detector 7 allows an image to be formed by light diffracting and/or scattering which occurs owing to the aerosol particles.

Referring to Figure 4, the ring detector 7 has a plurality of photo-sensors 70a ... 70n having semi-circular or circular light receptive surfaces on a base plate 70. The spatial intensity distribution of the aerosol particles caused by diffraction singly or diffraction and light scattering jointly is measured by obtaining the amplitude of the outputs of the photo-sensors 70a ... 70n.

The outputs of the photo-sensors 70a ... 70n in the ring detector 7 are digitized through an A/D converter (not shown) which are taken into a computer 8 at predetermined time intervals where necessary data alone are extracted from the data obtained in this way and stored in a storage 9 in accordance with a program which will be described hereinafter. The data

stored in the storage 9 is used to calculate the particle size distribution.

Referring to Figure 5, the measuring device is driven prior to starting the ejection of aerosol (A) through the ejector 1 and a predetermined number of photo-sensors 70a ... 70n are selected from those in the ring detector 7. The output data of the selected photosensors are temporarily stored in at ST1 and ST2 among which the maximum value A_{max} is searched at ST3.

The obtained maximum value D_{max} is compared with a predetermined value X_1 at ST4. This value X_1 is intended to detect the presence of particles between the optical system 5 and the condenser lens 6 through an increase in the spatial intensity of light incident to each photo-sensor due to the diffraction singly or the diffraction and scattering jointly. When the maximum value D_{max} does not reach the value X_1 , the same sequence from ST2 is repeated. When the maximum value A_{max} reaches the value X_1 , the sequence advances to a concentration checking routine at step ST5 and below.

In the concentration checking routine the number of times of measurements (N) is reset to 0 (zero)(ST5), and the data from the photo-sensors in the ring detectors 7 are temporarily stored to search the maximum value A_{max} at ST6 and ST7. At ST8 it is checked to see if the maximum value A_{max} is present between predetermined values X_2 and X_3 .

The values X_2 and X_3 correspond to the lower limit and the upper limit of an optimal range which determines an optimal range of the concentration of powdery solids. The relations between the maximum values A_{max} of outputs from the photo-sensors and the concentrations of powdery solids are shown in graph in Figure 6. It will be understood from the graph that the relations are proportional as seen from the straight line within the predetermined range of concentration. On the basis of this linear relationship the values X_2 and X_3 are set so as to correspond to the optimal measuring range.

At ST8, if it is found that the value A_{max} does not fall within the range defined by the values X_2 and X_3 , the sequence is returned to ST6 where the check is repeated. If it is found that the maximum value A_{max} exists between the values X_2 and X_3 , the sequence advances to ST9 on the understanding that the optimal measuring range is reached.

At ST9 and below where various concentration ranges are checked, when N (number of times of measurement) is 0 (zero), which means that the concentration of powdery solids falls within the optimal range for the first time after the measurement is initiated, the maximum value A_{max} is compared with a previous maximum value B_{max} if it exists, and if it does not exist, the maximum value A_{max} is compared with itself, a difference between the two maximum values is obtained, and compared with a value X_4 at ST11,

wherein the value X_4 determines a range covering a sudden or unexpected change likely to occur in the optimal measuring range, thereby negating data arising from such sudden change. If the difference ($A_{max} - B_{max}$) is equal to or smaller than the value X_4 , the data from all the photo-sensors temporarily stored at ST6 are stored in the storage 9 at ST12, and the maximum value A_{max} is stored at ST13 as the maximum value B_{max} for subsequent comparison. One is added to N (number of times) at ST14, and the same sequence below ST6 is repeated. When N is 0, meaning that A_{max} is equal to B_{max} , the data is stored.

When N is 1 and more, and if the concentration of powdery solids exceeds the allowable range with the result that the difference between A_{max} and B_{max} exceeds the value X_4 . The data are not stored, and the sequence from ST6 is repeated.

In this way the data is continuously stored in the storage 9 so long as the concentration of powdery solids is within the optimal range, and variation thereof, if any, remain within the allowable range after the previous data are stored. When the number of times (N) reaches X_5 times (normally a few hundreds of times), the data in the storage 9 are used, and particle size distribution is calculated by a known arithmetic method (ST15 and ST16).

The present invention measures particle size distribution with precision regardless of any variation occurring in the concentration of powdery solids ejected in aerosol through the ejector 1.

Instead of the concentration checking routine and the concentration allowable range checking routine, the latter can be omitted if the values X_2 and X_3 in the concentration checking routine are narrowly set so as to provide a narrow optimal range. If the maximum value A_{max} falls within this narrow range, it means that the value A_{max} is virtually the same as the value B_{max} . Thus the same effect is obtained as that resulting from the example described above.

Claims

1. A device for measuring particle size distribution of powdery solids, the device comprising:
 - 45 a laser for radiating laser beam upon a specimen of the powdery solids;
 - 50 an optical measuring system including a plurality of photosensors for measuring the spatial intensity distribution of diffracting and scattering light upon the specimen;
 - 55 an arithmetic unit for calculating a particle size distribution of the specimen on the basis of the spatial intensity distribution measured by the photo-sensors;
 - 60 a first judging means for monitoring outputs from a predetermined number of photo-sensors and seeing if the monitored outputs exceed

a first reference so as to know that the specimen are present in the optical measuring system;

a second judging means for storing the outputs of all the photo-sensors after the first judging means ascertains that the specimen is present in the optical measuring system, and seeing if a maximum value of the outputs falls within a range defined by a second reference and a third reference so as to know that the concentration of the specimen is optimal for measuring;

a storage for storing the outputs of all the photo-sensors as effective data only when the second means ascertains that the maximum value falls within the range defined by the second and third references; and

a third judging means for seeing if predetermined sets of effective data have been stored in the storage so as to operate the arithmetic unit.

2. The device according to claim 1, further comprising a fourth judging means for seeing if a difference between the maximum value of all the outputs of the photo-sensors and the previous maximum value is equal to or smaller than a fourth reference, during the period of time when the second judging means ascertains that the concentration of the specimen falls within a required range, wherein the storage stores all the outputs of the photo-sensors as effective data when the difference is equal to or smaller than the fourth reference.

3. The device according to claim 1 or 2, wherein the photosensors are constituted by ring detectors having different radii arranged concentric of an optical axis of the optical measuring system.

4. A method of measuring particle size distribution of powdery solids, wherein the powder is suspended in a gaseous medium and the spatial intensity distribution resulting from diffraction and scattering of a laser beam incident on the suspension is measured by means of photo-sensors, the particle size distribution being calculated as a function of the spatial intensity distribution, characterized in that the outputs from a predetermined number of photo-sensors are monitored to determine whether a powder specimen is present in the laser beam, the outputs from all the photo-sensors are monitored to determine whether a desired range of concentration of the powder is present, and the outputs of the sensors are stored for subsequent processing only when a powder specimen is present at a desired concentration.
